SUMMARY

Neuroimaging studies using diffusion tensor imaging (DTI) have revealed regions of cerebral white matter with decreased microstructural organization (lower-fractional anisotropy or FA) among poor readers. We examined whether 100 hr of intensive remedial instruction affected the white matter of 8- to 10-year-old poor readers. Prior to instruction, poor readers had significantly lower FA than good readers in a region of the left anterior centrum semiovale. The instruction resulted in a change in white matter (significantly increased FA), and in the very same region. The FA increase was correlated with a decrease in radial diffusivity (but not with a change in axial diffusivity), suggesting that myelination had increased. Furthermore, the FA increase was correlated with improvement in phonological decoding ability, clarifying the cognitive locus of the effect. The results demonstrate the capability of a behavioral intervention to bring about a positive change in cortico-cortical white matter tracts.

INTRODUCTION

A major challenge of cognitive neuroscience is to understand how changes in the structural properties of the brain underpin the plasticity exhibited whenever a person develops, ages, learns a new skill, or adapts to a neuropathology. Longitudinal studies have shown regional changes in the volume of gray matter that co-occur with skill acquisition or learning (Draganski et al., 2004, 2006), but there is also growing acknowledgment that higher-level cognition is based on co-functioning of a set of cortical areas in a dynamic large-scale network, highlighting the central role of cortical communication. Improved anatomical connectivity in motor tracts as measured by fractional anisotropy (FA) has been associated with enriched experience (extensive childhood piano practice) in a correlational study using diffusion tensor imaging (DTI) (Bengtsson et al., 2005). FA, which measures the anisotropy of the diffusion of water molecules (Basser and Pierpaoli, 1996), is sensitive to axonal density, size, myelination, and the coherence of organization of fibers within a voxel, and thus provides an index of the structural integrity of white matter.

Functional imaging studies have consistently demonstrated that children with reading disability display under-activation of a network of left-lateralized areas during reading, including occipito-temporal, temporo-parietal, and inferior frontal cortical regions (Hoeft et al., 2006, 2007; Meyler et al., 2007; Shaywitz et al., 2002; Simos et al., 2000a, 2000b), and that effective remedial reading interventions lead to increases in the activation in these same areas (Aylward et al., 2003; Meyler et al., 2008; Shaywitz et al., 2004; Simos et al., 2002; Temple et al., 2003), indicating that effective remediation can lead to a change in the brain functioning of poor readers. However, skilled reading depends not only on the activation of a set of relevant cortical areas, but also on communication among them. Reading diffi-culty has also been associated with lower functional connectivity (the synchronization of neural activity) across areas of the reading cortical network (Hampson et al., 2006; Horwitz et al., 1998; Pugh et al., 2000). This suggests that reading disability might be associated with structural properties of the white matter that provides the anatomical connectivity among the individual nodes of the reading network. Consistent with this view, several DTI studies of poor readers have found white matter regions with lower FA compared with controls (Beaulieu et al., 2005; Deutsch et al., 2005; Klingberg et al., 2000; Niogi and McCandliss, 2006; Odegard et al., 2009; Richards et al., 2008; Rollins et al., 2009). FA may be reduced in poor readers due to a number of possible differences in the microstructural properties of white matter, including reduced myelination, reduced axonal packing density, decreased axonal diameter, or reduced coherence of the orientation of axons within the region (Beaulieu, 2002; Ben-Shachar et al., 2007), all of which might impact the efficiency of communication (bandwidth) among cortical areas.

Here we report a longitudinal DTI study indicating that intensive remedial reading instruction (approximately 100 hr) can change the structural integrity of the cortical white matter of children who are poor readers. The children's DTI data were first assessed before instruction began and then a second time after the instruction ended, approximately 6 months later. At the preremediation scan, the poor readers showed significantly reduced fractional anisotropy (FA) in the anterior left centrum semiovale region, relative to a control group of good readers. Subsequent to the instruction, the remediated poor readers had not only made substantial gains in their reading ability, but...

also showed significantly increased FA in the anterior left centrum semiovale, in contrast to good readers and to a control group of untreated poor readers.

To help determine which microstructural properties had changed during remediation, we also examined the diffusivity in directions that are perpendicular to the principal axis of diffusion in anisotropic regions of white matter (radial diffusivity, \( \lambda_3 \)), or parallel to it (axial diffusivity, \( \lambda_1 \)). For example, changes in radial diffusivity in the absence of changes in axial diffusivity have been associated with changes in myelin (Beaulieu, 2002; Song et al., 2002, 2005), whereas changes in axial diffusivity in the absence of changes in radial diffusivity have been associated with an increase in axon diameter (Dougherty et al., 2007; but also see Wheeler-Kingshott and Cercignani [2009] for caveats about these measures). The results analyzed this way indicate that a behavioral intervention can bring about a positive change in the microstructure of human cortico-cortical white matter tracts, demonstrating the malleability of the anatomical connectivity that supports human cortical network function.

RESULTS

Forty-seven children (8–12 years old) who were poor readers were randomly assigned to either an intensive 100 hr program of systematic and explicit remedial reading instruction focused primarily on developing word-level decoding skills (n = 35), or they were assigned to a control group that received normal classroom instruction (n = 12). There was also a control group of good readers (n = 25) of the same age. The remedial instruction was distributed over about 6 months of schooling, with instruction occurring in groups of three children with one teacher. (Although the remedial instruction came in one of four alternative forms (see Experimental Procedures), there were no reliable differences among the children assigned to the different forms in either initial behavioral measures or DTI measures, nor in the impacts of the instruction (see Supplemental Results and Discussion, available online). Hence the data reported here are collapsed across the children in the four forms of remedial reading instruction.) The remediated and unremediated poor readers scored equivalently at the preinstruction scan on multiple measures of reading ability, whereas the group of good readers scored significantly better than both groups of poor readers on every reading ability measure (see Table S1). The behavioral results indicated that the poor readers who received the remedial instruction showed significant improvement on most of the age-standardized Woodcock Reading Mastery Test — Revised (WRMT-R, Woodcock et al., 1998) reading ability measures when retested following the instruction period, but that the control poor readers did not show improvement on these measures, indicated by a reliable overall group by time effect (\( F_{1, 45} = 4.36, p < 0.05 \)), with means shown in Table 1. Individual ANOVAs for each measure indicated that the interaction between group and time was reliable only for the subtest measuring non-word reading ability (Word Attack scores, \( F_{1, 45} = 5.22, p < 0.05 \)), but not for the subtests measuring real word reading ability (Word Identification) or passage comprehension ability (Passage Comprehension). This pattern of outcomes suggests that the instruction specifically improved phonological decoding skills more than the standard reading curricula did. This conclusion was also supported by an analysis of changes in raw scores on all ability measures collected from the poor readers before and after the treatment phase (see Supplemental Results and Discussion and Table S2).

The DTI results indicated that poor readers who received the remedial instruction showed a reliable increase in FA between the preremediation and postremediation scans, with a peak difference in the left anterior centrum semiovale, as shown in Figure 1A. Corresponding contrasts conducted for the two control groups that received no remedial instruction found no areas showing either an increase or decrease in FA between the two scans, indicating that the change in FA among the remediated poor readers was not due to maturational changes over the 6 month interval between the two scans. This same region also showed significantly reduced FA at the preremediation scan among all poor readers relative to the group of good readers (Figure 1B). The reliable increase in FA between the two scans among the poor readers, but no change in FA between
the scans among the good readers, nor among the unremediated poor reader controls, resulted in a significant group (3) by time (2) interaction with a peak F value in the same region of the left anterior centrum semiovale (Figure 2A), strongly suggesting that intensive remedial reading instruction led to changes in some microstructural property of white matter in a region of left frontal white matter, a region that differed between good and poor readers prior to the treatment. Additional analyses presented in the Supplemental Results confirmed that these findings were not due to the particular voxel-based analysis methods that were used; essentially identical results were obtained using unsmoothed data and nonparametric statistical inference methods (see Supplemental Results and Discussion and Figures S1 and S2).

Because increased FA in highly organized white matter can occur due to either a relative decrease in radial diffusivity or a relative increase in axial diffusivity (or both), a further analysis examined the remediation effect in each of these components separately in the region shown in Figure 2A. It was the radial diffusivity that had changed in the remediated poor readers subsequent to the instruction. There was a reliable group by time interaction for radial diffusivity in this same region (F2, 69 = 5.92, p < 0.005); this measure reliably decreased among the remediated poor readers (t(34) = 3.98, p < 0.0005), but showed no change in either the good readers or the poor reader controls, as shown in Figure 2C. This pattern of radial diffusivity effects mirrors the findings for FA (a reliable increase in FA among poor readers who received remedial instruction but no reliable change in FA among the two unremediated groups; Figure 2B). By contrast, the other component of FA, axial diffusivity, showed no significant changes between phases for any group at this location, nor was there a reliable interaction (Figure 2D). The no significant changes between phases for any group at this location, nor was there a reliable interaction (Figure 2D). The no significant changes between phases for any group at this location, nor was there a reliable interaction (Figure 2D). The no significant changes between phases for any group at this location, nor was there a reliable interaction (Figure 2D).

Neural Effects of Reading Remediation

change in radial diffusivity (pr = −0.23, p < 0.05) and change in SWE positively associated with the change (pr = 0.29). In contrast, for axial diffusivity, an identical stepwise regression analysis indicated that no change in any of the raw ability measures explained enough variance for entry into the model (p’s > 0.15). The outcome of these analyses indicate that there is a coupling between the behavioral change in reading and the anatomical change measured by FA and radial diffusivity, and indicates that increased phonological decoding ability provides the best predictor of increased FA and decreased radial diffusivity.

These results and conclusions are further supported by additional analyses (described in the Supplemental Results and Discussion) of the relationships between individual differences in various reading abilities and various diffusion tensor measures in the entire sample of good and poor readers, (using reading and diffusion measures obtained prior to the remediation), in the cluster that eventually showed an increase in FA among the remediated poor readers. Multiple regression analyses indicated that individual differences in phonological decoding ability (as measured by WRMT-R WA scores) were strongly positively related to FA (see Figure S3), strongly negatively related to radial diffusivity, and only weakly negatively related to axial diffusivity at the time of the preremediation scan (see Figure S4). These findings suggest that radial diffusivity drives the positive relationship between FA and individual differences in reading ability measured at the initial scan. In addition, both FA and radial diffusivity were more strongly related to Word Attack scores than to Word ID scores, suggesting that connections passing through the cluster area may be more important for phonological processing than for direct access to meaning via a direct orthographic route (see Supplemental Results and Discussion).

To determine the orientation of the tracts showing the remediation-related change and to identify the cortical areas that they likely connect, fiber tractography was carried out on group-averaged diffusion tensor data, using as a seed region the cluster of voxels showing a reliable group by time interaction. These group-averaged tracts were remarkably similar in their gross morphology between the good and poor readers and also across the two scanning sessions, as shown in Figure 3A, indicating the reliability of the data and the tracking methods. The principal direction of diffusion in the region showing a group difference in FA at the preremediation scan remained the same at the follow-up scan, and the fibers identified as passing through the regions were remarkably consistent between the two scans for both groups of subjects, suggesting that microstructural changes in the white matter within the region, rather than changes in the orientation of fibers, are responsible for the remediation effect and for the relationship of reading ability to the diffusion measures. The principal diffusion direction was anterior-posterior in all groups, and fibers passing through this region extended anteriorly and medially to terminate in a medial region of the superior frontal gyrus (Figure 3B) and extended posteriorly and superiorly to terminate in the left paracentral lobule (Figure 3C).

To check for consistency with previous DTI studies of white matter abnormalities among poorer readers in a left temporoparietal region (Beaulieu et al., 2005; Deutsch et al., 2005; Klingberg et al., 2000), we tested for group differences and a remediation effect in this region that had shown a relation to reading ability in these previous studies. Although there were no statistically reliable effects in the voxel-wise analyses, the FA was reliably lower among poor readers at the initial scan when the average FA across the entire region of interest was examined and the specific analysis was closely matched to those previous studies. A review of diffusion studies of this region (Ben-Shachar et al., 2007) suggests that the reduced FA among poorer readers is probably due to increased fiber crossings, and if this is indeed case, then intensive reading remediation would not be expected to change the coherence or the orientation of the fibers. Consistent with this expectation, there was no remediation effect in the region (see Supplementary Results and Discussion).

Figure 2. Differential Changes in Fractional Anisotropy as a Function of Group Are Due to Differences in Diffusivity Perpendicular to the Principal Diffusion Direction
(A) Location of the cluster of voxels with the maximum F value (peak F_{X, Y} = 9.66, spatial extent = 49 voxels, p < 0.0005 uncorrected, at MNI coordinates –12 26 40) for a test of the group by time interaction.

Neural Effects of Reading Remediation

The finding of longitudinally measured, experimentally mediated changes in the structural properties of left hemisphere white matter in children with reading problems reveals the considerable potential of behavioral remediation and rehabilitation programs, and furthers the understanding of reading disability and brain plasticity. The most important finding is clearly that both reading ability and the structural integrity of left hemisphere white matter can be increased by extensive practice in word decoding skills. This finding suggests that whatever the cause of abnormally low FA among poor readers may be, the abnormality is amenable to behavioral treatment when provided within an age window in which maturation, experience, and development are still capable of influencing FA.

The precise microstructural properties underlying both the initial group differences in FA and radial diffusivity and the remediation-related changes in these measures may be identifiable by further research. Among the factors influencing radial diffusivity are myelination, axonal packing density, and axon diameter (Beaulieu, 2002). One reason that myelination is a particularly attractive potential mechanism for future exploration is that myelin is known to affect primarily radial diffusivity (Song et al., 2002; Song et al., 2005). In addition, neuronal firing has been shown to affect myelination in central nervous system axons (Demerens et al., 1996; Ishibashi et al., 2006; Stevens et al., 2002). Although it is unknown whether such a mechanism could increase myelination in humans at the ages examined in the current study, it is possible that intensive training in word-reading skills increases the communication among left hemisphere cortical areas, which may in turn increase the myelination along the axons connecting these regions, decrease radial diffusivity along these axons, and increase FA. Methods exist for investigating this hypothesis concerning the role of myelination in the remediation effect using techniques such as magnetization transfer or T2 relaxation imaging for directly measuring myelin content.

It is tempting to ask about the causal directionality between the reading effects and the diffusion effects: does an increase in the efficiency of neural transmission resulting from remediation produce an increase in phonological decoding ability, or does increased phonological decoding ability produce increased reading behavior and consequent increases in the efficiency of the neural transmission? Both alternatives are possible, but it is also possible that the two types of changes develop interactively, as one might expect in a dynamic system like the brain. If the latter is the case, then it may be more fruitful to investigate factors that can accelerate or more finely control both the neuroplastic changes in white matter and the changes in reading processes, rather than attempting to determine the casual directionality.

The functional role in the reading process of the modified left anterior centrum semiovale white matter is not well understood, but it may pertain to the control processes of reading, rather than to word decoding itself. Activation in the left medial superior frontal gyrus occurs in normal children when processing orthographic and phonological forms of stimuli that are mutually inconsistent (Bitan et al., 2007), suggesting a response selection role for this area that may have been repeatedly evoked in the remedial phonological decoding tasks. The paracentral lobule has been found to activate more to phonologically dissimilar items than to similar items in a verbal memory task in adults (Sweet et al., 2008). Another control function associated with the paracentral lobule is as hub controller in the “structural core” of cortico-cortical axonal communication pathways (Hagmann et al., 2008), the nodes of which correspond to the “default mode” network (Raichle et al., 2001). It is possible that the repeated phonological processing in the remediation strengthened inhibitory connections between the paracentral lobule and medial frontal cortex, leading to reduced default network activity during reading. Although our findings do not illuminate the roles of the areas whose connectivity was improved, they nevertheless establish a structural change that could only have been brought about because of changes in activity in these areas or in secondarily connected areas.

The methodological question of how to accurately align the data from different participants for group analysis remains a topic of interest because of inherent limitations in regularizing unsystematic morphological variation. The limitations of the voxel-based approach used in the current study lie in its dependence on the accuracy of the coregistration algorithm and the amount of smoothing subsequently applied to the data to compensate for the inaccuracy (Jones et al., 2005; Smith et al., 2006). Recently developed alternative methods that attempt to avoid these particular concerns (Lee et al., 2009; Oakes et al., 2007; Smith et al., 2006) merit further evaluation, which is beyond the scope of the present paper. To address these limitations of the voxel-based approach, we have demonstrated that the main conclusions of the present study are also supported by analyses that do not use spatial smoothing or parametric assumptions (see Supplemental Results and Discussion and Figures S1 and S2).
Neuron

Neural Effects of Reading Remediation

The capability to improve white matter provides a possible remediation not only for reading difficulty but also for other neurological abnormalities believed to be underpinned by deficits in anatomical connectivity, such as autism (Just et al., 2007). Although the basic computing power of the brain surely lies in individual neurons, it is only their collective action, made possible by white matter connectivity, that enables the multicentered large-scale brain networks that characterize human thought. For this reason, modest modifications in white matter may enable major changes in cognitive ability.

EXPERIMENTAL PROCEDURES

Participants
Seventy-two participants were included in the analyses (35 poor readers that received the treatment, 12 poor readers that did not receive the treatment, and 25 good readers that did not receive the treatment). They were selected from a larger sample on the basis of their having provided functional and behavioral data used in an fMRI study of sentence comprehension (Meyler et al., 2007), and on their having artifact-free DTI data at both the preremediation and postremediation phases. The children gave verbal informed consent in the presence of a parent or guardian, who gave signed informed consent. The children were paid for their participation. A parent questionnaire was used to verify that all participants met inclusion criteria. All protocols were approved by the University of Pittsburgh and Carnegie Mellon University Institutional Review Boards.

The participants were all right-handed, native English-speaking children, with normal vision and hearing. Children were excluded from the study if they had brain injury, sensory disorders, psychiatric disorders, attention deficit disorder, metal in their bodies, were on medication, or were claustrophobic.

There were no differences in reading difficulties varying in severity (Torgesen et al., 2006). Criteria for inclusion in the project were a score at or above the 30th percentile on the combination of the sight word efficiency and phonological decoding subtests of the Test of Word Reading Efficiency (Torgesen et al., 1999) during its initial administration, and a score at or above the 5th percentile on the Peabody Picture Vocabulary Test (Dunn and Dunn, 1997). The good readers (designated as average to above average by their teachers) were recruited from the same schools.

Remedial Instruction
The main goal of the neuroimaging was to determine whether there was a relation between reading improvement and changes in white matter (regardless of the focus of the various remedial instruction programs). The poor readers were randomly assigned to either a control condition that did not include remedial instruction or to one of four remedial reading programs: Corrective Reading (n = 9), Wilson Learning System (n = 9), Spell Read Phonological Auditory Training (n = 10), and Failure Free Reading (n = 7). All of these programs provided systematic and explicit instruction in word-level decoding skills. Failure Free Reading focuses on developing recognition of words by sight, whereas the other three programs emphasize phonemic decoding. Additional detail about the specific instructional approaches and how they were implemented can be found elsewhere (Meyler et al., 2008; Torgesen et al., 2006).

The instruction was delivered 5 days per week for 50 min a day to groups of one to three students at a time, for a period of 6 months, providing a total of approximately 100 hr of intensive reading instruction.

Diffusion Tensor Imaging
Diffusion data were acquired on a 3T Siemens Allegro Scanner at the Brain Imaging Research Center of Carnegie Mellon and the University of Pittsburgh. A diffusion-weighted, double spin-echo, echo-planar imaging sequence was used to reduce effects of eddy currents, with TR = 4400 ms, TE = 74 ms, bandwidth = 2298 Hz/Voxel, FOV = 200 mm, and matrix size = 128 x 128. Thirty-six 3-mm-thick slices were imaged (no slice gap) with no diffusion weighting (b = 0 s/mm²) and with diffusion-weighting gradients applied in six orthogonal directions (b = 850 s/mm²). Twelve images of each slice by gradient direction (and b = 0) combination were acquired and averaged to produce the final diffusion imaging dataset for each participant. The FMRIB Diffusion Toolkit (v. 2.0, part of the FMRIB Software Library, http://www.fmrib.ox.ac.uk/fsl/) was used for motion and eddy current correction prior to analysis.

Data Analyses
Diffusion tensors and scalar diffusion parameter maps were calculated for each participant in native space using standard algorithms (Basser and Pierpaoli, 1996; Basser et al., 1994). For voxel-wise analyses, the diffusion tensor data were reduced to FA maps for each participant. For normalization of the DTI data to a standard space, a custom template was created from the T2-weighted b0 scans of all participants. SPM2 (Wellcome Department of Cognitive Neurology, London, UK) was used to first normalize each participant’s b0 volume to the Montreal Neurological Institute (MNI) EPI template using an affine transformation and 12 iterations of the default SPM2 nonlinear normalization algorithm. These normalized T2-weighted images were then averaged across all participants in both reading ability groups to produce a new template customized for the ages and reading abilities of the sample. Each participant’s original, native-space b0 volume was then normalized to this new template using the same algorithm, and the transformation parameters for this normalization were applied to the participant’s FA map and the maps for axial diffusivity (1/1) and radial diffusivity (1/2 + 1/3+2/3). For most of the analyses, the normalized maps for the three DTI scalar measures were spatially smoothed with an 8 mm FWHM Gaussian filter to accommodate imprecision of the normalization procedure, to improve signal to noise ratio, and to satisfy assumptions of Gaussian random field theory. Each participant’s DTI data were masked on the basis of their individual FA map at a threshold of 0.2 in order to restrict the analyses to white matter.

Analyses of standardized test scores were carried out in SAS (v. 9.1) software using mixed-effects analyses of variance (ANOVA) and paired or two-sample t tests, with corrections for multiple comparisons made by using a false discovery rate (Benjamini and Hochberg, 1995) of 5%, where appropriate (PROC MULTTEST). Voxel-wise statistical analyses of FA were carried out in SPM2 using the general linear model. Random-effects contrasts of FA data were carried out using Group (Good Reader Controls, Poor Reader Controls, and Remediated Poor Readers) as a between-subject variable and Instruction (Pre versus Post) as a within-subject variable. Reliable simple effects of Time within groups and Group within time are reported for clusters of voxels exceeding a voxel-level threshold of p < 0.005 (uncorrected) and a cluster size threshold of p < 0.05, corrected for multiple corrections in the context of random Gaussian field theory as implemented in SPM2. Additional random effects multiple regression analyses were carried out within the preremediation and postremediation phases of the experiment and for postremediation minus preremediation difference images, with age and raw reading scores entered as continuous independent predictor variables. Voxel-wise nonparametric tests reported in the Supplemental Results and Discussion were carried out using the Randomise (v. 1.2) tool included in version 4.1 of the FMRIB Software Library (FSL, http://www.fmrib.ox.ac.uk/fsl/) with 5000 permutations and default neighborhood connectivity parameters for the threshold-free cluster enhancement option for multiple comparison correction. FA and axial and radial diffusivity were also analyzed by extracting the scalar values from each subject for each voxel showing reliable effects on FA, and the values averaged across voxels were submitted to mixed-effects ANOVAs and multiple regression analyses (SAS PROC MIXED) and to stepwise hierarchical regression analyses (SAS PROC REG). Stepwise regressions were conducted using the default options of the REG procedure for variable entry and removal (p < 0.15 for both).

To produce an averaged diffusion tensor dataset for each group at each phase of the study, a 12 parameter affine multiple regression analyses were carried out within the b0 scan for each participant and the b0 template created above. This affine transformation was then applied separately to each component of the participant’s diffusion tensor dataset, the spatially transformed components were recombined for each subject, and the eigenvectors of the resulting tensor data were reoriented using the preservation of principal directions (PPD) method (Alexander et al., 2001) as implemented in the Camino software package (Cook et al., 2006). The individual components were then averaged
across participants within each group at each phase, and the resulting averaged and reoriented components were recombined to produce a group-averaged diffusion tensor data set. Deterministic streamline fiber tracking of group-averaged diffusion tensor data was carried out using a modified version of the FACT algorithm (Mori et al., 1999) as implemented in Camino, using a curvature threshold of 70 degrees and a liberal anisotropy threshold of 0.05 to allow estimated fibers to penetrate gray matter in order to better characterize the possible cortical and subcortical regions connected by the estimated fibers. Tractography was seeded using the cluster showing a group by time interaction for the FA data at the preremediation phase shown in Figure 2A.

**SUPPLEMENTAL DATA**

Supplemental Data include four figures, two tables, and Supplemental Results and Discussion, and can be found with this article online at http://www.cell.com/neuron/supplemental/S0896-6273(09)00847-2.

**ACKNOWLEDGMENTS**

This research was supported by grants from the R.K. Mellon Foundation, the National Institute of Mental Health (Grant MH029617), and the William and Flora Hewlett Foundation. Participants were recruited through the Power4Kids program, which is a public-private partnership including the Haan Foundation for Children; Institute of Education Sciences, U.S. Department of Education; Heinz Endowments; Smith Richardson Foundation; W.K. Kellogg Foundation; Grable Foundation; Rockefeller Foundation; Ambrose Monell Foundation; Raymond Foundation; and Barksdale Reading Institute. We thank Anne Meyler for help with data collection and collation, Kwan-Jin Jung and Vladimir Cher-kassky for technical assistance, Cindy Haan and Joe Torgesen for leadership of the Power4Kids program, and Donna Durno, Rosanne Javorsky, and the Allegheny Intermediate Unit for their central coordinating efforts throughout the project.
